PURPOSE OF THE ABSTRACT

Biocatalysis is emerging as an environmentally friendly and cost-effective alternative to the chemocatalytic synthesis of chiral amines. Directed evolution is the method of choice for optimizing biocatalysts but is often time consuming and its success is unpredictable. To meet the fast pace of product development in industry the turnaround time of engineering enzymes needs to become shorter. Here we present a workflow for rapid large-scale sequence–function data generation and show that this data can guide and thereby accelerate enzyme engineering. As a model system we chose an imine reductase (IRED) from S. roseum (SrIRED) catalysing reductive amination. To rapidly assess the fitness of >10000 IRED variants, we developed a cheap and versatile absorbance-activated droplet sorting-based ultra-high throughput screening setup. Coupled to a novel deep sequencing protocol combining next generation- and long-read-sequencing, this workflow allows the generation of large-scale fitness data using unbiased mutagenesis by error-prone PCR and the resolution of epistasis in less than 2 weeks. Using this novel workflow, we identified hot spots for engineering substrate specificity in the active site and at the periphery of the enzyme. We used higher-order mutation data to score the combinability of individual improving mutations and rationally engineered highly active variants (10-fold improved kcat/KM) displaying positive epistasis showing that our workflow can give rapid access to highly improving variants. Due to its versatility and broad applicability, we envision that this workflow will become a valuable part of the protein engineer's toolkit for rapid enzyme engineering.
